ABSTRACT

Genetic polymorphisms of IGF1, GH, and OPN genes in crosses Peranakan Ongole cattle based on birth type in Central Java. JITV 22(4): 165-172. DOI: http://dx.doi.org/10.14334/jitv.v22i4.1625

Genetic polymorphisms of IGF1, GH, and OPN genes in crosses Peranakan Ongole cattle based on birth type in Central Java. JITV 22(4): 165-172. DOI: http://dx.doi.org/10.14334/jitv.v22i4.1625

Polimorfisme genetik dari gen IGF1, GH, dan OPN pada sapi berdasarkan tipe kelahiran di Jawa Tengah. Polimerfisme genetik dari gen IGF1, GH dan OPN pada sapi berdasarkan tipe kelahiran di Jawa Tengah. Perbaikan produktivitas dengan cara menyilangkan sapi PO terhadap sapi potong eksotik melalui kawin IB disukai banyak peternak di Jawa Tengah. Fertilitas menentukan kemampuan seekor induk sapi dalam menghasilkan anak. Gen IGF1 diduga mempengaruhi kelahiran kembar dan ganda pada sapi, sedangkan gen GH dan OPN menentukan kesuburan reproduksi. Polimorfisme genetik ketiga gen ini dipelajari pada sapi PO silangan untuk kelahiran tunggal (T) dan kelahiran (histori) kembar dan ganda (G) berasal dari dua kabupaten di Jawa Tengah, yaitu dari Sragen (T = 7 ekor, dan G = 13 ekor) dan dari Kendal (T = 9 ekor, dan G = 16 ekor). Polimorfisme genetik dideteksi dengan metode RFLP (polymerase chain reaction - restriction fragment length polymorphism) menggunakan enzim restriksi SnaBI (gen IGF1), MSpI (gen GH), dan BsrI (gen OPN). Lokus IGF1|SnaBI dari sapi PO silangan yang diamati tidak memberikan varian SNP atau bersifat monomorfik untuk tipe kelahiran tunggal maupun kembar dan ganda. Sebaliknya lokus GH|MSpI dan OPN|BsrI bersifat polimorfik dengan tingkat keragaman cukup tinggi. Disimpulkan lokus IGF1|SnaBI tidak bisa dipakai untuk melihat kemungkinan adanya kontrol genetik kelahiran kembar (ganda), tetapi lokus GH|MSpI dan OPN|BsrI bisa dipertimbangkan sebagai informasi awal untuk seleksi molekul pada sifat kesuburan dari sapi potong.

Kata Kunci: Sapi Potong, Polimorfisme Genetik, Gen Kesuburan

Genetic Polymorphisms of IGF1, GH, and OPN Genes in Crossbred of Peranakan Ongole Cattle Based on Birth Type in Central Java. Improved productivity by crossing Peranakan Ongole (PO) cattle to exotic beef cattle through AI mating is preferred by many farmers in Central Java. Fertility determines the ability of a cow to give birth. IGF1 gene is predicted to affect either twin or multiple births in cattle, whereas GH and OPN genes determine reproductive fertility. Genetic polymorphisms of these three genes were studied in the crossbred of PO cattle for single birth (S) as well as twin and multiple (M) births or their historical (H) ones from two districts in Central Java, from Sragen (S = 7 hd and M = 13 hd.) and from Kendal (S = 9 hd and M = 16 hd.). Genetic polymorphisms were identified by RFLP (polymerase chain reaction - restriction fragment length polymorphism) method using restriction enzymes of SnaBI (IGF1 gene), MSpI (GH gene), and BsrI (OPN gene). IGF1|SnaBI locus in the observed crossbred PO did not have SNP polymorphism or monomorphic for single and twins or multiple births. In contrast, GH|MSpI and OPN|BsrI loci were polymorphic with quite a high degree of diversity. In conclusion, the IGF1|SnaBI locus cannot be used to investigate possible genetic control of twins and multiple births, whilst GH|MSpI and OPN|BsrI polymorphisms can be considered as initial information for selection on fertility traits in beef cattle.

Key Words: Beef Cattle, Genetic Polymorphism, Fertility Genes
INTRODUCTION

Beef cattle have a strategic role in producing red meat for the national population. Java Island is one of the centers of national beef cattle agribusiness, with the highest beef cattle population in the year 2016, as an example, are from East Java 4,407,807 hd., Central Java 674,573 hd., West Java 413,372 hd., and Yogyakarta Special Regency 309,018 hd respectively (DGLAH 2017). Central Java thus becomes one of the national beef cattle production. Animals are mostly raised by small farmers under a cow-calf system (CCO) system. Crossbreeding through artificial insemination technique is preferred especially by farmers in many areas in Central Java. This is due to adequate facilities and human resources (inseminator) in supporting the easy implementation for artificial insemination (AI) mating. The crossing is preferred because farmers like calves to grow rapidly to give heavier weights, compared to those calves of local beef cattle. Crosses by AI mating are usually performed between local Peranakan Ongole (PO) cattle by the frozen semen of exotic beef cattle bulls mainly from Bos taurus, such as Simmental, Limousine, and Brahman.

The ability of reproduction of a cow to produce a calf within a short calving interval (around 12 months) is crucial for the success of beef cattle agribusiness. Another aspect that is also interesting to note, is to see the chances of twinning or multiple births in beef cattle. Large ruminant is very well known as uniparous species. It is very common for beef cattle to have a single calf in one birth (Komisarek & Dorynek 2002; Çobanoğlu 2010). However, at a low level, incidences of cows calving twins or multiple calves per birth occur. The natural frequency of twin and multiple parutions in cattle ranges from 0.5-4% depending on many genetic and environmental factors (Sawa et al. 2012). Many studies have reported the cows of having twinning and multiple births without extra management and health services could cause detrimental for both cow and calves. Some negative effects from twin and multiple pregnancies were for decreasing fertility of cows by causing longer calving interval by 18 d., reproductive rest period by 9 d., and service period by 10 d., as well as increasing services per conception by 0.15 (Sawa et al. 2012). Twins and multiple births cause to lessen overall cow reproductive efficiency and productivity. However, twinning and multiple calves can give profitability under an intensive beef cattle breeding condition. Twinning or multiple births were possible to improve biological efficiency and production as a result of lower input costs during pregnancy and lactation cows (Karlsen et al. 2000).

Using molecular technology makes it possible to identify possible genes for having the control on twins and multiple births in beef cattle. Twins and multiple births in cows are known as a trait that follows a quantitative pattern, controlled by many genes. In addition, reproductive traits have many limitations for genetic improvement due to low heritability, sex-related expression, and difficult phenotypic measurements (Singh et al. 2014). The molecular selection at DNA level may help to get an earlier decision-making of animals to be considered as breeding stocks. Many studies have investigated genetic polymorphisms of major genes in relation to their effect on fertility. A number of growth and reproductive genes are predicted to affect twins and multiple births in cattle. Those genes are thought in affecting the number of ova produced and the number of transferable embryos, leading as potential gene markers for superovulation response (Yang et al. 2010; Deb et al. 2012; Singh et al. 2014).

Twinning rate in cattle is basically a sequential product of ovulation rate, conception rate, and embryo survival. Twinning and ovulation rates in cattle are strongly genetically correlated (0.75–0.9) (Gregory et al. 1997). This indicates the two traits are influenced by common loci (Lien et al. 2000). Certain variant SNPs or genotypes of IGF1 gene are presumed for having genetic control on twins and multiple births in beef cattle. A study by Echternkamp et al. (1990) proved that twinning and multiple pregnancies in cattle is associated by the increasing IGF-1 concentrations in both blood serum and follicular fluid. The IGF-1 stimulates mitogenesis of granulosa cells and steroidogenesis of ovarian cell cultures. This gene plays an important role in the regulation of folliculogenesis and may be involved in the process of multiple ovulations in cattle. IGF1 gene stimulates ovarian function by acting with gonadotropins to promote growth and steroidogenesis of ovarian cells (Lucy 2001). This is essential in stimulating multiple ovulation rates to give potential twins or multiple pregnancies during the process of fertilization.

GH and OPN genes are two of the other genes that play another role in maintaining twins and multiple pregnancies in cattle. Their roles are to give success on conception rate and embryo survival. Osteopontin (OPN) gene in cattle is located at chromosome 6 (BTA6) closed to quantitative trait loci (QTL) of fertility and milk production (Leonard et al. 2005). OPN is known as secreted phosphoprotein 1 (SPP1). OPN is expressed on maternal and foetal interface suggesting indicating that OPN gene has an important role in maintaining uterine-embryonic microenvironment (Johnson et al. 2003). This gene has the function to profoundly impact pregnancy, embryo implantation and placental development (Li et al. 2013). Whereas Growth Hormone (GH) gene plays a key role in postnatal growth and developments in tissue, muscle, bone, adipose tissue, udder gland (Sami et al. 2011). GH gene is involved in the processes of sexual
differentiation and pubertal maturation as well as participated in gonadal steroidogenesis, gametogenesis and ovulation. This gene has additional roles in pregnancy and lactation through the actions as reflecting direct endocrine actions of pituitary GH or be mediated by its induction of hepatic or local IGF-I production (Hull & Harvey 2001). Significant relationships have been reported between GH concentrations and postpartum period and fertility of cows (Lucy 2008).

This study was aimed to investigate genetic polymorphisms of IGF1, OPN and GH genes in the crossbred PO cattle from two districts in Central Java Province. Information on genetic polymorphisms at certain DNA fragments of IGF1, OPN, and GH genes can be useful to investigate possible genetic control of twins and multiple births as well as fertility traits in beef cattle.

MATERIALS AND METHODS

Beef cattle as samples

Animals as samples in this study were crossed Peranakan Ongole (PO) cattle as the offsprings of crossbreeding PO females to exotic beef cattle breeds such as Simmental, Limousin, and Brahman. The crossed PO cattle were observed from Sragen Regency and Kendal Regency in Central Java Province. A female or a cow determined of having twins or multiple births was that cow for giving twins or multiple births at least once during her life, while that of historical twin or multiple births was that animal calved from twins or multiple births. Abbreviation of cows having (historical) twins or multiple births called M, whilst cow with single birth was grouped as control (S). A total number of the crossed PO cattle observed from Sragen amounted by 20 hd., consisting of the cows having twins or multiple births (M) by 13 hd. (9 females and 4 males), while those with single birth (S) by 7 hd. (all females). Further, the total number of the crossed PO cattle from Kendal were 25 hd, consisting the cows having twins or multiple births (M) by 16 hd (15 females, 1 male), while cows having single birth (S) by 9 hd. (4 females, 5 males).

Blood collection

All of those crossed PO cattle as samples were collected their fresh blood. Blood samples were taken for DNA analysis collected from jugular vein using a 21 G X 1 ½ sized vacutainer or 10 ml syringe containing heparin anticoagulant substance. A total of 1 to 2 ml of blood samples was stored in a 10 ml tube and added 8 ml of ethanol (EtOH) absolute containing 1 mM EDTA.

DNA extraction

DNA extraction was done by following four steps. 1. Sample preparation: 200 μl blood sample was inserted into 1.5 ml tube, added by distilled water 1000 μl, and centrifuged at 8000 rpm for 5 min. 2. Degradation of protein: 1xSTE sample was added to a solution of 350 μl, 40 μl SDS 10% and 10 μl proteinase K 5 mg/ml and incubated at 55°C for 2 hours. 3. Degradation of organic matter: the solution was added to 400 μl of phenol, 400 μl chloroform-isooamyl alcohol (24: 1) and 40 μl NaCl, then gently whisked at a room temperature for 1 hour. 4. DNA precipitation was performed by adding: 400 μl supernatant added 40 μl NaCl 5 M and 800 μl ethanol absolute, homogenized, frozen overnight.

DNA amplification

DNA genomes of the crossed PO cattle from single birth and twin (multiple) births were used as template in DNA amplification reaction (PCR reaction). The primer used for IGF1 gene, namely forward 5’- CCTCTGCGGGGCTGAGTTGGT-3’ and reverse 5’- CGACTTGGCGGGCTTGAGAGGC-3’ following Siadkowska et al (2006). Primer used for Osteopontin (OPN) gene, namely forward GCAAATCAGAAGTGTGATAGAC-3’ and reverse CCAAGCAAACGTATGAGTT-3’ following Leonard et al. (2005). While Growth Hormone (GH) gene used two pairs of primers, namely forward GCCAATCAGAAGTGTGATAGAC-3’ and reverse CCAAGCGAAACGTATGAGTT-3’ following Leonard et al. (2005). While Growth Hormone (GH) gene used two pairs of primers, namely forward CCC ACG GGC AAG GC and GAG AAG; and reverse TGA GGA ACT GCA GGG GCC CA in accordance to Zhou et al. (2005).

PCR reaction

PCR reaction was performed with a total volume of 25 μl of solution mixture comprising Taq Polymerase DNA and 10X Taq Polymerase buffer (100 mM Tris-Cl, pH 8.3, 500mM KCl; 15mM MgCl2; 0.01% gelatin); dNTP’S mix (dGTO, dATP, dTTP and dCTV) (Pharmacia); and sterile dH2O. While PCR reaction conditions in the thermocycler engine were designed with pre-denaturation temperature by 93°C, denaturation by 94°C, annealing by 58-60°C, extension by 72°C, and post PCR 4°C. Cycles were repeated 33 times for multiplication.
Genotyping

To detect genetic variants of specific base fragments of each IGF1, OPN and GH genes were performed by PCR 5 μl product added 1 μl distillation water, 0.7 μl buffer, and restriction enzyme 0.3 μl, then incubated at 37°C for 16 h. DNA cutting products were visualized on 2% agarose gel with 0.5 x TBE buffer (Tris-Borate EDTA, then coloured ethidium bromide. Electrophoretic results were observed with the aid of UV light transilluminator.

Analysis of genetic polymorphism

Analysis of genetic polymorphism or SNPs (single nucleotide polymorphisms) from each locus of IGF1|SnaBI GH|Msp1 and OPN|BsrI were conducted by Poggene 32 packet programme for:

a. Genotype and allele frequency by computing genotype number of all genotypes in a population
b. Hardy-Weinberg (H-W) Equilibrium by testing Chi-Square calculation
c. Heterozygosity observation (Ho) and expectation (He) by estimating on the base on allele frequency
d. Shannon's Information index

RESULTS AND DISCUSSION

Genotyping genes

SNP polymorphisms in IGF1 gene to be considered as potential molecular markers for economic traits providing reproduction traits (Leonard et al. 2005; Lucy 2008; Sami et al. 2011; Singh et al. 2014). DNA amplification of IGF1, OPN, and GH genes using PCR techniques by following specific primer design was successfully performed on all blood samples of the crossed PO cattle observed. Amplification products were obtained for single birth as well as twins and multiple births of the crossed PO cattle from Sragen (S = 9 hd, and M = 13 hd.) and also from Kendal (S = 9 hd, and M = 16 hd).

IGF1 gene

Bovine IGF1 gene is located on chromosome 5 (BTA5) at nucleotide positions 66,532,877- 66,604,734 (UMD_3.1, Chromosome, Bos taurus, Ensembl) with the provisional nucleotide sequence is approximately 72 kb (ID number 281239) (Reyna et al. 2010). DNA amplification was performed at intron 1 of IGF1 gene that resulted in a DNA fragment size by 249 bp (Siadkowska et al. 2006). Amplicon products were genotyped by SnaBI restriction enzyme. However, SnaBI enzyme did not cut specific DNA cutting sites at the intron 1 of IGF1 of all the crossed PO cattle observed. This happened both for single birth as well as for twins and multiple births from the two locations. Genotyping IGF1|SnaBI locus in the crossed PO cattle produced only one fragment of 249 bp. This means that all these animals had only one type of genotype, namely BB genotype. In contrast, there was not found either AA genotype (223 and 26 bp) or AB genotype (249, 223 and 26 bp). None of the genetic variation or SNP of IGF1|SnaBI locus was possibly due to no C/T base transition as a specific cutting site of SnaBI restriction enzyme.

OPN gene

Bovine OPN gene or SPP1 gene comprises 7 exons spanning about 7 kb of genomic DNA (GenBank accession number NW 255516). OPN gene is composed of 6961 bp in total length: 1331 bp in processed length and 278 in protein product lengths. DNA amplicons of OPN gene were cut by a BsrI enzyme to detect a point mutation at specific base fragment at intron 4. Genetic polymorphism of OPN gene was studied by following Leonard et al. (2005) that found a C/T transition at intron 4 in a non-code 5 region of OPN gene in Bos taurus cattle. Amplification products of DNA fragments of OPN|BsrI locus resulted in a base fragment size by 290 bp. For restricting DNA fragments of OPN|BsrI locus into two DNA bands by 200 and 90 bp was expressed as CC genotype. While, CT genotype was identified for the occurrence of three DNA bands by 290, 200, and 90 bp. If the DNA amplicons was not cut off by restriction enzyme resulting only one DNA band by 290 bp for TT genotype resulted.

GH gene

PCR products of GH gene were cut by the Msp1 enzyme to detect a point mutation at intron 3 of GH gene. When DNA fragments at intron 3 of GH gene after the cutting by the Msp1 enzyme produced two bands by 223 bp and 104 bp, so it was identified as BB genotype. For the producing only one DNA band by 327 bp was called AA genotype. When the existing three DNA bands of 327 bp, 223 pb, and 104 bp were named AB genotype. Results from this study were consistent to the previous study by Khatib et al. (2009) for identifying three AA, AB, and BB genotypes from the GH|Msp1 gene in Bos taurus dairy cattle.

Genotype and allele frequency

Genetic diversity is expressed as the total number of genetic characters that build the genetic makeup of a species, breed or population. Genetic diversity serves as a way for populations to adapt to changing environments. While more genetic variations exist, it is
Anggareni et al. Genetic polymorphisms of IGF1, GH, and OPN genes in crosses Peranakan Ongole cattle based on birth type in Central Java

more likely that animals will have a better adaptation to the environment. Cattle is a diploid organism that has two potential alleles at a particular fragment of a gene. If a cattle have the same allele, it is expressed as homozygous, otherwise to be heterozygous. A codominant allele is very useful to serve as a genetic marker. The frequency of alleles and genotypes can reflect genetic diversity of animal population.

As previously stated that genotyping intron 1 of IGF1|SnaBI locus on all of the crossed PO cattle in this study produced the only BB genotype with the DNA fragment of 249 bp. This means each individual of both historical twin (multiple) births and the single birth of the crossed PO cattle from the two locations had the only BB genotype (Table 1). Thus only the B allele was found (1,000), otherwise no A allele. An allele is said to be monomorphic if that allele frequency is more than 0.99. No genetic variation or monomorphic of the specific base cutting site, known as C/T base transition, at intron 1 of IGF1|SnaBI locus was identified. Certain SNPs or genotypes of IGF1 gene are presumed for having genetic control in stimulating multiple ovulation rates to give potential twins or multiple pregnancies (Echterkamp et al. 1990; Gregory et al. 1997; Singh et al. 2014). By the finding monomorphic base at the specific base of SnaBI cutting site from this results indicated that IGF1|SnaBI locus cannot be used to investigate possible genetic control of twins and multiple births in the crossbred PO cattle.

Several studies, however, identified an SNP at the intron 1 of IGF1 using a SnaBI restriction enzyme showing a T>C transition at the specific cutting site of SnaBI restriction enzyme in Cattle. Frequently B allele was reported dominant than A allele showing that BB cattle very dominant to those AA and AB cattle. Yurnalis et al. (2017) from a study in local Pesisir cattle in West Sumatera reported frequencies of AA, AB, and BB genotypes were successively 0.0125, 0.0125, and 0.9750 and resulted frequencies of A and B alleles were 0.00625, and 0.99375 respectively. Genetic polymorphism of IGF1 gene was also reported from Bali cattle of which an SNP as a transition mutation T/C being identified by restriction enzyme Rsal at exon 4 with the frequency of C allele higher than that of T allele, namely 0.836 vs. 0.164 (Maskura et al. 2012). Furtherly genotyping IGF1 by PCR – RFLP method using TaqI and MspI restriction enzymes and amplification-created restriction site (ACRS) one by SnaBI, TaqI and TaqI restriction enzymes in Poland Cattle, Szewczuk (2016) reported frequencies of the most common alleles 0.67 for T allele (IGF1|SnaBI), 0.85 for A allele (IGF1|TaqI), 0.95 for C allele (IGF1R|TaqI), 0.84 for G allele (IGF1R|MspI) and 0.69 for G allele (IGF1R|TaqI).

Genotyping at intron 4 of OPN|BsrI polymorphism in the crossed PO cattle did not produce CC genotype for both single and twins or multiple births for the two locations. Single birth cattle in both locations had higher frequencies of TT genotype (0.750 to 1.000) than CT genotype (0.000 - 0.250). Whilst for twins and multiple births ones had higher frequencies of TT genotype (0.750 to 1.000) than CT one (0.333 - 0.529). These results suggested that single birth had more common for homozygous BB cattle, whereas twins and
multiple births were more frequent in heterozygous CT
cattle. High CT and TT genotypes resulted in higher T
allele against C allele for both single birth or twins and
multiple births of the crossed PO cattle in this study.
Pareek et al. (2008) reported OPN or SPP1 C>T SNP
polymorphism was also found within the intron IV of
bovines SPP1 gene that was investigated in selected
breeds of beef (Hereford and Limousine) and dairy
(Polish HF and Polish Red) cattle. The study revealed
significant differences in the distribution of C and T
alleles among the analysed panel of cattle breeds. In
general allele frequencies of T and C were 0.59 and
0.41 respectively; so frequencies of TT, CT and CC
genotypes were 34.69, 48.62, and 16.69 respectively.

Growth hormone (GH) is an anabolic hormone
synthesized and secreted by somatotropic cells in an
anterior pituitary lobe (Ayuk & Sheppard 2006). The
specific DNA cutting site at intron 3 of GH|MspI locus
lies at position 1547 (Zhang et al. 1993). Genotyping
DNA fragments at intron 3 of GH|MspI SNP polymorphism in the crossed PO cattle in twin and
multiple births had higher frequencies of AB genotype
(0.417 - 0.471) and BB genotype (0.412 - 0.500) than
AA genotype (0.083 - 0.118). The same pattern was
found in single birth type. AB cattle were found higher
than AA one. Even in Kendal, single birth cattle was
just identified only for BB genotype. These results
indicated that both single birth and twins (multiple)
births of the crossed PO cattle had higher AB and BB
genotype than AA one. Thus frequencies of B allele
were higher than those of A allele A across birth type
and location. DNA polymorphism of GH|MspI locus in
Aceh cattle was reported by Putra et al. (2013) to have
only TT genotype (BB genotype) resulting frequency of
T allele was 1,000 and monomorphic.

### Heterozygosity

Estimation of heterozygosity value was obtained to
determine the level of genetic diversity in the crossed
PO cattle population observed. This information can be
used to help the effectiveness of selection program on
breeding stocks to be used as a genetic source in the
next generation (Marson et al. 2005). Heterozygosity
observation (Ho) of OPN|BsrI and GH|MspI loci of the
crossed PO cattle by birth type are listed in Table 2.
Heterozygosity expectation (He) is required to know the
difference to heterozygosity observation (Ho). For the
IGF1|SnaBI locus with the only BB genotype in all of
the crossed PO cattle lead to Ho value of 0.000.

For OPN|BsrI locus in the crossed PO cattle from
both locations showed Ho values were higher than He
values. It was for single birth namely Ho = 0.2857
- 0.4286 vs He = 0.2637 - 0.3626; while that for multiple
births, namely Ho = 0.6000 - 0.6667 vs He = 0.4345
- 0.4638. Ho values were higher than the He values from
this OPN|BsrI locus could be an indication for a good
heterozygosity level this gene polymorphism in the
crossed PO cattle either for single birth and twins or
multiple births. OPN|BsrI locus, therefore, could be
considered as a molecular selection in regarding
increase probability of twins or multiple births in beef
cattle. According to Javanmard et al. (2005), a
heterozygosity value above 0.5 (50%) indicates a high
variation of a gene in a population. Molecular selection
by using OPN|BsrI gene might be possible to give a
good selection respond in improving twin or multiple
births in beef cattle.

However, the opposite result was found to GH|MspI
locus in which the crossed PO cattle in multiple births
had relatively smaller Ho values compared to He
values, i.e Ho = 0.3636 - 0.4375 vs He = 0.4156
- 0.4657. This indicated heterozygosity level of GH|MspI

</table>
locus was relatively low in twin and multiple births in both locations. Generally, OPN|BsrI and GH|MspI loci had high polymorphic level (100%), the exception was for GH|MspI for the single birth type from Kendal which was monomorphic with only the BB genotype.

**Hardy-Weinberg equilibrium**

Chi-square analysis can be used to determine whether or not the genotype frequency ($p^2$, $2pq$, $q^2$) or allele frequencies ($p$ and $q$) in a population. The results of Chi-square analysis can be used as an indicator of population equilibrium known as Hardy-Weinberg Equilibrium. Chi-square value ($\chi^2$) of OPN|BsrI locus in the crossed PO cattle showed significantly different ($\chi^2>\chi^2$ (0.05)) for single and multiple births in both locations, excepting for single birth in Kendal. It can be stated that allele frequency of OPN|BsrI locus of the crossed PO cattle was in equilibrium for twins and multiple births from both locations.

$\chi^2$ value of the crossed PO cattle of GH|MspI locus from single birth type could not calculate because of it was monomorphic. Genotype frequencies in the crossed PO cattle, therefore, did not meet the assumptions for Hardy-Weinberg equilibrium analysis. Furthermore, GH|MspI polymorphism in multiple births in both locations had Chi-Square values higher ($\chi^2>\chi^2$ (0.05)), so it can be stated that these two populations were in Hardy – Weinberg equilibrium. This means that mating among individual cattle from twins and multiple births in both locations was in equilibrium. A population can be stated in a Hardy-Weinberg equilibrium if the frequency of dominant and recessive alleles are constant from generation to generation, there is no selection, mutation, migration, and genetic drift.

### CONCLUSION

Genotyping intron 1 of IGF1|SnaBI locus on all of the crossed PO cattle in this study produced the only BB genotype with the DNA fragment of 249 bp. By the finding monomorphic base at the specific base of SnaBI cutting site from this results indicated that IGF1|SnaBI locus cannot be used to investigate possible genetic control of twins and multiple births in the crossbred PO cattle. Whilst genotyping GH|MspI and OPN|BsrI loci were polymorphic that useful as initial information for molecular selection on fertility traits in beef cattle. GH|MspI locus in the crossed PO cattle from multiple births was in equilibrium H-W equilibrium contrasting to OPN|BsrI locus indicating that the frequencies of AA and BB alleles of GH|MspI were constant by generations.
